BIOLOGICAL CONTROL OF FLOWERING RUSH

Locations  
Canada, United States

Dates  
01/01/2013 - Ongoing

Summary  
Attractive pink flowers make the Eurasian plant flowering rush a popular aquatic ornamental. But since it was introduced to North America it has become an aggressive invader of freshwater systems in the midwestern/ western USA and western Canada. One likely reason for this is the absence of the natural enemies that keep it in check in its area of origin. CABI is searching for natural enemies that could be introduced to reduce its vigour and spread in North America.
The problem

Flowering rush (*Butomus umbellatus*) was introduced from temperate Eurasia to North America as an ornamental aquatic plant more than 100 years ago. It escaped cultivation and spread in the wild to become a severe problem in freshwater systems of the midwestern/western states of the USA and in western Canada with multiple impacts. Infestations can increase maintenance costs in irrigation ditches and impede recreational activities along rivers and lake shores. The plant provides habitat for the great pond snail, which hosts parasites that cause ‘swimmer’s itch’ (a skin rash caused by an allergic reaction). Dense stands of the plant may also benefit introduced non-native fish that spawn in vegetated substrate to the detriment of native fish.

No effective control techniques are currently available.

What we are doing

We started a biological control project at CABI in 2013. Our aim is to find specific natural enemies and assess their suitability for release as biological control agents in North America, where they could reduce the vigour and limit the spread of flowering rush.

The ideal biological control agent is very specific and inflicts serious damage to the target host plant. The specificity of a natural enemy reflects how closely its evolution has been linked to that of its host (how coevolved they are). Surveying in the area of origin of a target weed is a good way of finding coevolved natural enemies.

By reviewing the literature and carrying out field surveys in the weed’s area of origin in Europe, we identified several organisms that look sufficiently promising to warrant in-depth investigations. We are currently establishing rearing colonies and are studying their biology, host specificity and impact on flowering rush to evaluate their potential as biological control agents.
Results so far

Our field surveys range from the UK, the Netherlands, northern Germany, to the Czech and Slovak Republics, Poland, Hungary, Serbia, Georgia and Kazakhstan.

The semi-aquatic weevil, *Bagous nodulosus*, is currently our most promising candidate. Its larvae feed on the leaves and rhizomes of flowering rush. Although it was reported to be rare, we have collected it at over 25 sites so far. We have established a rearing colony at CABI’s centre in Switzerland, although we are still having problems with high larval mortality. In no-choice oviposition tests (offering females only a test species or the target weed) with 45 species, *B. nodulosus* has so far only accepted one other plant species, the European *Baldellia ranunculoides*, for egg-laying besides flowering rush. This confirms that the weevil has a very narrow host range. Since learning that larvae commonly leave the host plant and swim to infest surrounding flowering rush plants, we started no-choice larval establishment tests in 2018. After testing 41 species, we found limited feeding and larval development on only three species, *Alisma plantago-aquatica*, *Limnobium laevigatum*, and *Hydrocharis morsus-ranae*. All three are of European origin. An impact experiment carried out in 2019 showed a reduction in total biomass by 25% when plants were exposed to adult weevils which was mainly due to a reduction in below-ground biomass (33%). We are planning to submit a petition for *B. nodulosus* to be released in North America in the near future together with our North American partners.

We are also studying an agromyzid fly, *Phytoliriomyza ornata*, we have established a rearing colony and started host-specificity tests. Results, so far, look promising.

In 2016, we started work with a white smut fungal pathogen, *Doassansia niesslii*, which is able to infect completely submerged plants of flowering rush. The methodology of storage and application of the white smut is being studied at CABI’s UK centre and host-specificity testing has started. *D. niesslii* has shown to be specific at the genotype level. Therefore, the main concern is to find a strain that can attack the most common genotypes of flowering rush present in North America.
