Summary

*Alphitobius diaperinus* is one of the most predominant poultry litters inhabiting insect species all over the world. It has been shown to be able of transmitting a large variety of poultry pathogenic organisms.

The spatial distribution and the population fluctuation of *Alphitobius diaperinus* have been studied in a broiler house during a raising cycle in the Province of Constantine (North-East of Algeria). The total larvae trapped increased from the first to the fifth week, and then decreased over the 02 last weeks, whereas adults caught increased from week 1 to week 7. Larvae were more abundant in all of the samples. No correlation was found between insects' counts, temperature and humidity records. The environmental conditions (28.60°C and 86.91% H²O) within the broiler house allowed *A. diaperinus* to complete its life cycle during the breeding period. By the first week the insect population was concentrated in quarter the surface of the facility, and then it spread through the half by week 3, 4, 5 and 6. About 70% of the population was concentrated in the edges of the breeding zone and 30% in its centre. The results of this study may help the implementation of a chemical treatment to control this insect.

Introduction

*Alphitobius diaperinus* is one of the most predominant poultry litters inhabiting insect species all over the world. It has been shown to be able of transmitting a large variety of poultry pathogenic organisms, such as viral agents (IBDV...) [7], bacterial disease organisms (*Salmonella spp., Campylobacter spp...*) [9] and several poultry parasites.

Understanding the biology, the epidemiology and the behaviour of this insect is primordial to determine its control measures.

In this paper, we have studied the spatial distribution and the population fluctuation of *Alphitobius diaperinus* in a broiler breeding house during a raising cycle in the Province of Constantine (North-East of Algeria).

Material and Methods

The breeding house. The study was carried out between February and March 2008 in a naturally infested greenhouse-like poultry house located in the Community of Hamma Bouziane, Province of Constantine (North-East of Algeria). It is 08 m wide by 48 m long, earth floored with sides made of multiple layers of reed and straw covered with a plastic foil. It held one flock of 3000 chicken for 50 days. No chemical treatment was used and the litter consisted of wood shavings.
Insect sampling. Adults and larvae *A. diaperinus* were sampled using the sandwich-type traps (wooden boxes of 20 cm / 15 cm / 8 cm, with cover and two openings of 1 cm in the longitudinal direction, next to base of the box. The traps are filled with corrugated paper) [8]. Traps were placed at 04 locations across the house and 8 locations down the house. At each location, temperature (at 06 cm depth) and humidity (at the surface) of the litter were measured using a digital hygro-thermometer (OREGON SCIENTIFIC, model ETHG913R). The contents of the traps were collected weekly in plastic bags and then frozen. The traps were refilled with new corrugated paper after each collection. Beetles and larvae counts and environmental data (temperature and humidity) were recorded with correct corresponding spatial coordinates.

Spatial distribution. Contour plots of insects were obtained by using the geostatistical software Golden Surfer 8 [5] with the kriging algorithm, a statistical linear method estimating the best value based on weighted linear combinations of neighbouring values while aiming to minimize the error variance between samples.

Results

Population fluctuation (Fig.1). The total larvae trapped increased from the first week to the fifth week, then decreased through week 6 and 7, whereas adults increased from week 1 to the end. Larvae were more abundant in all of the samples. Temperature beneath the litter was always approximately similar during the first six weeks then decreased by the seventh week. Humidity showed a more or less comparable evolution.

Fig. 1: Population fluctuation of larvae and adults of Alphitobius diaperinus related to the T° and H° of the litter.
Spatial distribution (Fig. 2). By the first week the insect population was concentrated in quarter the surface of the facility, and then it spread through the half by week 3, 4, 5 and 6. By the seventh week the population moved far from the southern side of the house. 70% of the population was concentrated in the edges of the breeding zone (Which represents 6% of its total surface) and 30% in its centre. Insects’ concentration in the brooder section was not correlated to the poultry distribution, which was not uniform all over the house.

The earth floor is an excellent medium where eggs can be deposited and final instars tunnel and pupate. The facility sides are also ideal for pupating. The insects hide in earth floor and insulation materials (reed and straw) during the depopulation period, and then emerge by the start of a new flock.

Discussion

The average temperature and humidity during the raising period (28.60 °C and 86.91%) are ideal to the development of the different stages of this insect. Its life cycle could be achieved in 70 to 89 days at 27 °C and 65% [4] and in 26 days at 31 °C [1]. This explains the fact that the number of immature forms in our results reached its maximum by the 5th week, and decreased by week 6 and 7 during what larvae became pupa then adults. As in Chernaki-Lefler et al’s findings, the results of our study proved that there is no correlation between the numbers of trapped insects and temperature records [2]. Lambkin et al, in compact earth flour, reported that the number of lesser mealworms increased over the 14 first days, picking at 16 and declined over the 28 last days [6]. Strother and Steelman found darkling beetle populations initially concentrated along the perimeter of the house and spread toward the centre as population density increased [10]. Lower densities are found in open locations.
and under drinkers, while high densities occurred under feeders, support pillars and along the house edges. [3,6].

**Conclusion**

The greenhouse-like poultry house provides an excellent environment to the installation, the development and the spread of the darkling beetle *A. diaperinus*. Further studies seem to be necessary to understand the biology and the behaviour of this insect in this type of poultry houses along the year.
